#### Abstract

An orientable sequence of order $n$ is a cyclic binary sequence such that each length- $n$ substring appears at most once in either direction. Maximal length orientable sequences are known only for $n \leq 7$, and a trivial upper bound on their length is $2^{n-1}-2^{\lfloor(n-1) / 2\rfloor}$. This paper presents the first efficient algorithm to construct orientable sequences with asymptotically optimal length; more specifically, our algorithm constructs orientable sequences via cycle-joining and a successor-rule approach requiring $O(n)$ time per symbol and $O(n)$ space. This answers a longstanding open question from Dai, Martin, Robshaw, Wild [Cryptography and Coding III (1993)]. Our sequences are applied to find new longest-known orientable sequences for $n \leq 20$.

## 1 Introduction

Orientable sequences were introduced by Dai, Martin, Robshaw, and Wild [6] with applications related to robotic position sensing. In particular, consider an autonomous robot with limited sensors. To determine its location on a cyclic track labeled with black and white squares, the robot scans a window of $n$ squares directly beneath it. For the position and orientation to be uniquely determined, the track must designed with the property that each length $n$ window can appear at most once in either direction. A cyclic binary sequence (track) with such a property is called an orientable sequence of order $n$ (an $\mathcal{O} \mathcal{S}(n)$ ). By this definition, an orientable sequence does not contain a length- $n$ substring that is a palindrome.

Example 1 Consider $\mathcal{S}=001011$. In the forward direction, including the wraparound, $\mathcal{S}$ contains the six 5 -tuples $00101,01011,10110,01100,11001$, and 10010 ; in the reverse direction $\mathcal{S}$ contains $11010,10100,01001,10011$, 00110, and 01101. Since each substring is unique, $\mathcal{S}$ is an $\mathcal{O S}(5)$ with length (period) six.

Orientable sequences do not exist for $n<5$, and somewhat surprisingly, the maximum length $M_{n}$ of an $\mathcal{O S}(n)$ is known only for $n=5,6,7$. Since the number of palindromes of length $n$ is $2^{\lfloor(n+1) / 2\rfloor}$, a trivial upper bound on $M_{n}$ is $\left(2^{n}-2^{\lfloor(n+1) / 2\rfloor}\right) / 2=2^{n-1}-2^{\lfloor(n-1) / 2\rfloor}$.

In addition to providing a tighter upper bound, Dai, Martin, Robshaw, and Wild [6] provide a lower bound on $M_{n}$ by demonstrating the existence of $\mathcal{O S}(n)$ s via cycle-joining with length $L_{n}$ (defined in Section 1.1) asymptotic to their upper bound. They conclude by stating the following open problem relating to orientable sequences whose lengths (periods) attain the lower bound. See Section 1.1 for the explicit upper and lower bounds.

> We note that the lower bound on the maximum period was obtained using an existence construction ... It is an open problem whether a more practical procedure exists for the construction of orientable sequences that have this asymptotically optimal period.

Recently, some progress was made in this direction by Mitchell and Wild [25]. They apply Lempel's lift [22] to obtain an $\mathcal{O S}(n)$ recursively from an $\mathcal{O S}(n-1)$. This construction can generate orientable sequences in $O(1)$-amortized time per symbol; however, it requires exponential space, and there is an exponential time delay before the first bit can be output. Furthermore, they state that their work "only partially answer the question, since the periods/lengths of the sequences produced are not asymptotically optimal."

Main result: By developing a parent rule to define a cycle-joining tree, we construct an $\mathcal{O S}(n)$ of length $L_{n}$ in $O(n)$ time per bit using $O(n)$ space.

Outline. In Section 1.1, we review the lower bound $L_{n}$ and upper bound $U_{n}$ from [6]. In Section 2, we present necessary background definitions and notation, including a review of the cycle-joining technique. In Section 3, we provide a parent rule for constructing a cycle-joining tree composed of "reverse-disjoint" cycles. This leads to our $O(n)$ time per bit construction of orientable sequences of length $L_{n}$. In Section 4 we discuss the algorithmic techniques used to extend our constructed orientable sequences to find longer ones for $n \leq 20$. We conclude in Section 5 with a summary of our results and directions for future research. An implementation of our construction is available for download at http://debruijnsequence.org/db/orientable.

### 1.1 Bounds on $M_{n}$

Dai, Martin, Robshaw, and Wild [6] gave a lower bound $L_{n}$ and an upper bound $U_{n}$ on the maximum length $M_{n}$ of an $\mathcal{O} \mathcal{S}(n) .{ }^{1}$ Their lower bound $L_{n}$ is the following, where $\mu$ is the Möbius function:

$$
L_{n}=\left(2^{n-1}-\frac{1}{2} \sum_{d \mid n} \mu(n / d) \frac{n}{d} H(d)\right), \quad \text { where } \quad H(d)=\frac{1}{2} \sum_{i \mid d} i\left(2^{\left\lfloor\frac{i+1}{2}\right\rfloor}+2^{\left\lfloor\frac{i}{2}\right\rfloor+1}\right)
$$

Their upper bound $U_{n}$ is the following: ${ }^{1}$

$$
U_{n}= \begin{cases}2^{n-1}-\frac{41}{9} 2^{\frac{n}{2}-1}+\frac{n}{3}+\frac{16}{9} & \text { if } n \bmod 4=0, \\ 2^{n-1}-\frac{31}{9} 2^{\frac{n-1}{2}}+\frac{n}{3}+\frac{19}{9} & \text { if } n \bmod 4=1, \\ 2^{n-1}-\frac{41}{9} 2^{\frac{n}{2}-1}+\frac{n}{6}+\frac{20}{9} & \text { if } n \bmod 4=2, \\ 2^{n-1}-\frac{31}{9} 2^{\frac{n-1}{2}}+\frac{n}{6}+\frac{43}{18} & \text { if } n \bmod 4=3\end{cases}
$$

These bounds are calculated in Table 1 for $n$ up to 20. This table also illustrates the length $R_{n}$ of the $\mathcal{O S}(n)$ produced by the recursive construction by Mitchell and Wild [25], starting from an initial orientable sequence of length 80 for $n=8$. The column labeled $L_{n}^{*}$ indicates the longest known orientable sequences we discovered by applying a combination of techniques (discussed in Section 4) to our orientable sequences of length $L_{n}$.

| $n$ | $R_{n}$ | $L_{n}$ | $L_{n}^{*}$ | $U_{n}$ |
| ---: | ---: | ---: | ---: | ---: |
| 5 | - | 0 | $\mathbf{6}$ | 6 |
| 6 | - | 6 | $\mathbf{1 6}$ | 17 |

### 1.2 Related work

Recall the problem of determining a robot's position and orientation on a track. Suppose now that we allow the track to be non-cyclic. That is, the beginning of the track and the end of the track are not connected. Then the corresponding sequence that allows one to determine orientation and position is called an aperiodic orientable sequence. One does not

[^0]consider the substrings in the wraparound for this variation of an orientable sequence. Note that one can always construct an aperiodic $\mathcal{O S}(n)$ from a cyclic $\mathcal{O S}(n)$ by taking the cyclic $\mathcal{O S}(n)$ and appending its prefix of length $n-1$ to the end. See the paper by Burns and Mitchell [4] for more on aperiodic orientable sequences, which they call aperiodic 2-orientable window sequences. Alhakim et al. [2] generalize the recursive results of Mitchell and Wild [25] to construct orientable sequences over an alphabet of arbitrary size $k \geq 2$; they also generalize the upper bound, by Dai et al. [6], on the length of an orientable sequence. Rampersad and Shallit [26] showed that for every alphabet size $k \geq 2$ there is an infinite sequence such that for every sufficiently long substring, the reversal of the substring does not appear in the sequence. Fleischer and Shallit [11] later reproved the results of the previous paper using theorem-proving software. See [5, 23] for more work on sequences avoiding reversals of substrings.

## 2 Preliminaries

Let $\mathbf{B}(n)$ denote the set of all length- $n$ binary strings. Let $\alpha=\mathrm{a}_{1} \mathrm{a}_{2} \cdots \mathrm{a}_{n} \in \mathbf{B}(n)$ and $\gamma=\mathrm{g}_{1} \mathrm{~g}_{2} \cdots \mathrm{~g}_{\mathrm{m}} \in \mathbf{B}(m)$ for some $m, n \geq 0$. Throughout this paper, we assume $0<1$ and use lexicographic order when comparing two binary strings. More specifically, we say that $\alpha<\gamma$ either if $\alpha$ is a prefix of $\gamma$ or if $\mathrm{a}_{\mathrm{i}}<\mathrm{g}_{\mathrm{i}}$ for the smallest $i$ such that $\mathrm{a}_{\mathrm{i}} \neq \mathrm{g}_{\mathrm{i}}$. The weight (density) of a binary string is the number of 1 s in the string. Let $\overline{\mathrm{a}}_{i}$ denote the complement of bit $\mathrm{a}_{i}$. Let $\alpha^{R}$ denote the reversal $\mathrm{a}_{n} \cdots \mathrm{a}_{2} \mathrm{a}_{1}$ of $\alpha ; \alpha$ is a palindrome if $\alpha=\alpha^{R}$. For $j \geq 1$, let $\alpha^{j}$ denote $j$ copies of $\alpha$ concatenated together. If $\alpha=\beta^{j}$ for some non-empty string $\beta$ and some $j>1$, then $\alpha$ is said to be periodic ${ }^{2}$; otherwise, $\alpha$ is said to be aperiodic ${ }^{3}$. A necklace class is an equivalence class of strings under rotation; let $[\alpha]$ denote the set of strings in $\alpha$ 's necklace class. We say $\alpha$ is a necklace if it is the lexicographically smallest string in $[\alpha]$. Let $\mathbf{N}(n)$ denote the set of length- $n$ necklaces. A bracelet class is an equivalence class of strings under rotation and reversal; let $\langle\alpha\rangle$ denote the set of strings in $\alpha$ 's bracelet class. Thus, $\langle\alpha\rangle=[\alpha] \cup\left[\alpha^{R}\right]$. We say $\alpha$ is a bracelet if it is the lexicographically smallest string in $\langle\alpha\rangle$.

A necklace $\alpha$ is palindromic if it belongs to the same necklace class as $\alpha^{R}$, i.e., both $\alpha$ and $\alpha^{R}$ belong to $[\alpha]$. By this definition, a palindromic necklace is necessarily a bracelet. If a necklace or bracelet is not palindromic, it is said to be apalindromic. Let $\mathbf{A}(n)$ denote the set of all apalindromic bracelets of order $n$. Table 2 lists all 60 necklaces of length $n=9$ partitioned into apalindromic necklace pairs and palindromic necklaces. The apalindromic necklace pairs belong to the same bracelet class, and the first string in each pair is an apalindromic bracelet. Thus, $|\mathbf{A}(9)|=14$. In general, $|\mathbf{A}(n)|$ is equal to the number of necklaces of length $n$ minus the number of bracelets of length $n$; for $n=6,7, \ldots 15$, this sequence of values $|\mathbf{A}(n)|$ is given by $1,2,6,14,30,62,128,252,495,968$ and it corresponds to sequence A 059076 in The On-Line Encyclopedia of Integer Sequences [31]. Apalindromic bracelets have been studied previously in the context of efficiently ranking/unranking bracelets [1]. One can test whether a string is an apalindromic bracelet in linear time using linear space; see Theorem 1.

- Theorem 1. One can determine whether a string $\alpha$ is in $\mathbf{A}(n)$ in $O(n)$ time using $O(n)$ space.

Proof. A string $\alpha$ will belong to $\mathbf{A}(n)$ if $\alpha$ is a necklace and the necklace of $\left[\alpha^{R}\right]$ is lexicographically larger than $\alpha$. These tests can be computed in $O(n)$ time using $O(n)$ space [3].

- Lemma 2. A necklace $\alpha$ is palindromic if and only if there exists palindromes $\beta_{1}$ and $\beta_{2}$ such that $\alpha=\beta_{1} \beta_{2}$.

Proof. Suppose $\alpha$ is a palindromic necklace. By definition, it is equal to the necklace of $\left[\alpha^{R}\right]$. Thus, there exist strings $\beta_{1}$ and $\beta_{2}$ such that $\alpha=\beta_{1} \beta_{2}=\left(\beta_{2} \beta_{1}\right)^{R}=\beta_{1}^{R} \beta_{2}^{R}$. Therefore, $\beta_{1}=\beta_{1}^{R}$ and $\beta_{2}=\beta_{2}^{R}$, which means $\beta_{1}$ and $\beta_{2}$ are palindromes. Suppose there exists two palindromes $\beta_{1}$ and $\beta_{2}$ such that $\alpha=\beta_{1} \beta_{2}$. Since $\beta_{1}$ and $\beta_{2}$ are palindromic, we have that $\alpha^{R}=\left(\beta_{1} \beta_{2}\right)^{R}=\beta_{2}^{R} \beta_{1}^{R}=\beta_{2} \beta_{1}$. So $\alpha$ belongs to the same necklace class as $\alpha^{R}$ and hence is palindromic.

- Corollary 3. If $\alpha=0^{s} \beta$ is a palindromic bracelet such that the string $\beta$ begins and ends with 1 and does not contain $0^{s}$ as a substring, then $\beta$ is a palindrome.

### 2.1 Cycle-joining

Given $\mathbf{S} \subseteq \mathbf{B}(n)$, a universal cycle $U$ for $\mathbf{S}$ is a cyclic sequence of length $|\mathbf{S}|$ that contains each string in $\mathbf{S}$ as a substring (exactly once). Thus, an orientable sequence is a universal cycle. If $\mathbf{S}=\mathbf{B}(n)$ then $U$ is known as a de Bruijn sequence. Given a universal cycle $U$ for $\mathbf{S}$, a $U C$-successor for $U$ is a function $f: \mathbf{S} \rightarrow\{0,1\}$ such that $f(\alpha)$ is the symbol following $\alpha$ in $U$.

Cycle-joining is perhaps the most fundamental technique applied to construct universal cycles; for some applications, see $[8,9,10,12,14,16,17,29,30]$. If $\mathbf{S}$ is closed under rotation, then it can be partitioned into necklace classes (cycles); each cycle is disjoint. Let $\alpha=\mathrm{a}_{1} \mathrm{a}_{2} \cdots \mathrm{a}_{n}$ and $\hat{\alpha}=\overline{\mathrm{a}}_{1} \mathrm{a}_{2} \cdots \mathrm{a}_{n}$; we say $(\alpha, \hat{\alpha})$ is a conjugate pair. Two disjoint cycles can be joined if they each contain one string of a conjugate pair as a substring. This approach resembles Hierholzer's algorithm to construct an Euler cycle in an Eulerian graph [15].

Example 2 Consider disjoint subsets $\mathbf{S}_{1}=[011111] \cup[001111]$ and $\mathbf{S}_{2}=[010111] \cup[010101]$. Then $U_{1}=$ 110011110111 is a universal cycle for $\mathbf{S}_{1}$ and $U_{2}=01010111$ is a universal cycle for $\mathbf{S}_{2}$. Since $(110111,010111)$ is a conjugate pair, $U=110011110111 \cdot 01 \underline{10111}$ is a universal cycle for $\mathbf{S}_{1} \cup \mathbf{S}_{2}$.

If all necklace cycles can be joined via conjugate pairs to form a cycle-joining tree, then the tree defines a universal $U$ for $\mathbf{S}$ with a corresponding UC-successor (see Section 3 for an example).

For most universal cycle constructions, a corresponding cycle-joining tree can be defined by a rather simple parent rule. For example, when $\mathbf{S}=\mathbf{B}(n)$, the following are perhaps the simplest parent rules that define how to construct cycle-joining trees with nodes corresponding to $\mathbf{N}(n)$ [13, 27].

- Last-0: rooted at $1^{n}$ and the parent of every other node $\alpha \in \mathbf{N}(n)$ is obtained by flipping the last 0 .
- First-1: rooted at $0^{n}$ and the parent of every other node $\alpha \in \mathbf{N}(n)$ is obtained by flipping the first 1.
- Last-1: rooted at $0^{n}$ and the parent of every other node $\alpha \in \mathbf{N}(n)$ is obtained by flipping the last 1.
- First-0: rooted at $1^{n}$ and the parent of every other node $\alpha \in \mathbf{N}(n)$ is obtained by flipping the first 0 .

These rules induce the cycle-joining trees $\mathrm{T}_{1}, \mathrm{~T}_{2}, \mathrm{~T}_{3}, \mathrm{~T}_{4}$ illustrated in Figure 1 for $n=6$. Note that for $\mathrm{T}_{3}$ and $\mathrm{T}_{4}$, the parent of a node $\alpha$ is obtained by first flipping the highlighted bit and then rotating the string to its lexicographically least
rotation to obtain a necklace. Each node $\alpha$ and its parent $\beta$ are joined by a conjugate pair, where the highlighted bit in $\alpha$ is the first bit in one of the conjugates. For example, the nodes $\alpha=011011$ and $\beta=001011$ in $\mathrm{T}_{2}$ from Figure 1 are joined by the conjugate pair $(110110,010110)$.

Figure 1 Cycle-joining trees for $\mathbf{B}(6)$ from simple parent rules.

## 3 An efficient cycle-joining construction of orientable sequences

Consider the set of apalindromic bracelets $\mathbf{A}(n)=\left\{\alpha_{1}, \alpha_{2}, \ldots, \alpha_{t}\right\}$. Recall, that each palindromic bracelet is a necklace. Let $\mathbf{S}(n)=\left[\alpha_{1}\right] \cup\left[\alpha_{2}\right] \cup \cdots \cup\left[\alpha_{t}\right]$. From [6], we have $|\mathbf{S}(n)|=L_{n}$. By its definition, there is no string $\alpha \in \mathbf{S}(n)$ such that $\alpha^{R} \in \mathbf{S}(n)$. Thus, a universal cycle for $\mathbf{S}(n)$ is an $\mathcal{O S}(n)$. For the rest of this section, assume $n \geq 8$.

To construct a cycle-joining tree with nodes $\mathbf{A}(n)$, we apply a combination of three of the four simple parent rules described in the previous section. First, we demonstrate that there is no such parent rule, using at most two rules in combination. Observe, there are no necklaces in $\mathbf{A}(n)$ with weight $0,1,2, n-2, n-1$, or, $n$. Thus, $0^{n-4} 1011$ and $0^{n-5} 10011$ are both necklaces in $\mathbf{A}(n)$ with minimal weight three. Similarly, $00101^{n-4}$ and $001101^{n-5}$ are necklaces in $\mathbf{A}(n)$ with maximal weight $n-3$. Therefore, when considering a simple parent rule for a cycle-joining tree with nodes $\mathbf{A}(n)$, the rule must be able to flip a 0 to a 1 , or a 1 to a 0 , i.e., the rule must include one of First- 0 or Last- 0 , and one of First-1 and Last-1.

Let $\alpha=\mathrm{a}_{1} \mathrm{a}_{2} \cdots \mathrm{a}_{n}$ denote a necklace in $\mathbf{A}(n)$; it must begin with 0 and end with 1 . Then let

- first1 $(\alpha)$ be the necklace $\mathrm{a}_{1} \cdots \mathrm{a}_{i-1} 0 \mathrm{a}_{i+1} \cdots \mathrm{a}_{n}$, where $i$ is the index of the first 1 in $\alpha$;
- last1 $(\alpha)$ be the necklace of $\left[a_{1} a_{2} \cdots a_{n-1} 0\right]$;
- first0 $(\alpha)$ be the necklace of $\left[1 \mathrm{a}_{2} \cdots \mathrm{a}_{n}\right]$;
- last $0(\alpha)$ be the necklace $\mathrm{a}_{1} \cdots \mathrm{a}_{j-1} 1 \mathrm{a}_{j+1} \cdots \mathrm{a}_{n}$, where $j$ is the index of the last 0 in $\alpha$.

Note that first1 $(\alpha)$ and last0 $(\alpha)$ are necklaces (easily observed by definition) obtained by flipping the $i$-th and $j$-th bit in $\alpha$, respectively; last $1(\alpha)$ and first $0(\alpha)$ are the result of flipping a bit and rotating the resulting string to obtain a necklace. The next example illustrates that no two of the simple parent rules can be applied in combination to obtain a spanning tree with nodes in $\mathbf{A}(n)$.

Example 3 Suppose $\mathrm{p}(\alpha)$ is a parent rule that applies a combination of the four simple parent rules to construct a cycle-joining tree with nodes $\mathbf{A}(n)$. The following examples are for $n=10$ but generalize to larger $n$. In both cases, we see that at least three of the simple parent rules must be applied in p .

Suppose p does not use First-0; it must apply Last-0. Consider three apalindromic bracelets in $\mathbf{A}(10)$ : $\alpha_{1}=0000001011, \alpha_{2}=0000010111$, and $\alpha_{3}=0011001011$. Clearly, first1 $\left(\alpha_{1}\right)$, last1 $\left(\alpha_{1}\right)$, and last0 $\left(\alpha_{1}\right)$ are palindromic. Thus, $\alpha_{1}$ must be the root. Both first1 $\left(\alpha_{2}\right)$ and last $0\left(\alpha_{2}\right)$ are palindromic; thus, p must apply Last-1. Note last $0\left(\alpha_{3}\right)$ is palindromic and last $1\left(\alpha_{3}\right)=0001100101$ is not a bracelet; thus, p must apply First- 1 .

Suppose $p$ does not use Last-0; it must apply First-0. Consider three apalindromic bracelets in $\mathbf{A}(10)$ : $\beta_{1}=0000100011, \beta_{2}=0001001111$, and $\beta_{3}=0001100111$. Clearly, $\operatorname{first} 1\left(\beta_{1}\right), \operatorname{last} 1\left(\beta_{1}\right)$, and first0 $(\beta)$ are palindromic. Thus, $\beta_{1}$ must be the root. Both first $1\left(\beta_{2}\right)$ and first $0\left(\beta_{2}\right)$ are palindromic; thus, p must apply Last-1. Both last1 $\left(\beta_{3}\right)$ and first0 $\left(\beta_{3}\right)$ are palindromic; thus, p must apply First-1.

Let $r_{n}$ denote the apalindromic bracelet $0^{n-4} 1011$.

Parent rule for cycle-joining $\mathbf{A}(n)$ : Let $r_{n}$ be the root. Let $\alpha$ denote a non-root node in $\mathbf{A}(n)$. Then

$$
\operatorname{par}(\alpha)= \begin{cases}\operatorname{first} 1(\alpha) & \text { if first1 }(\alpha) \in \mathbf{A}(n) ;  \tag{1}\\ \operatorname{last1}(\alpha) & \text { if first1 }(\alpha) \notin \mathbf{A}(n) \text { and last1 }(\alpha) \in \mathbf{A}(n) \\ \operatorname{last0}(\alpha) & \text { otherwise }\end{cases}
$$

- Theorem 4. The parent rule $\operatorname{par}(\alpha)$ in (1) induces a cycle-joining tree with nodes $\mathbf{A}(n)$ rooted at $r_{n}$.

Let $\mathbb{T}_{n}$ denote the cycle-joining tree with nodes $\mathbf{A}(n)$ induced by the parent rule in (1); Figure 2 illustrates $\mathbb{T}_{9}$. The proof of Theorem 4 relies on the following lemma.
-Lemma 5. Let $\alpha \neq r_{n}$ be an apalindromic bracelet in $\mathbf{A}(n)$. If neither first1 $(\alpha)$ nor last $1(\alpha)$ are in $\mathbf{A}(n)$, then the last 0 in $\alpha$ is at index $n-2$ or $n-1$, and both last0( $\alpha)$ and last1 $(\operatorname{last} 0(\alpha))$ are in $\mathbf{A}(n)$.

Proof. Since $\alpha$ is an apalindromic bracelet, it must have the form $\alpha=0^{s} 1 \beta 01^{v}$ where $s, v \geq 1$ and $\beta 0$ does not contain $0^{s+1}$ as a substring. Furthermore, $1 \beta 01^{v}<\left(1 \beta 01^{v}\right)^{R}$, which implies $\beta 01^{v-1}<\left(\beta 01^{v-1}\right)^{R}$.
Suppose $v>2$. Since last $1(\alpha)=0^{s+1} 1 \beta 01^{v-1}$ is not an apalindromic bracelet, we have $1 \beta 01^{v-1} \geq\left(1 \beta 01^{v-1}\right)^{R}$. Thus, $\beta$ begins with 1. Since first $1(\alpha)=0^{s+1} \beta 01^{v}$ is not an apalindromic bracelet, Lemma 2 implies $\beta 01^{v} \geq\left(\beta 01^{v}\right)^{R}$, contradicting the earlier observation that $\beta 01^{v-1}<\left(\beta 01^{v-1}\right)^{R}$. Thus, the last 0 in $\alpha$ is at index $n-2$ or $n-1$.
Suppose $v=1$ or $v=2$. Let $j$ be the index of the last 0 in $\alpha$. Since $\alpha$ is a bracelet, it is straightforward to see that $\operatorname{last} 0(\alpha)=\mathrm{a}_{1} \cdots \mathrm{a}_{n}$ is also a bracelet. If it is palindromic, Lemma 2 implies there exists an index $i$ such that $\beta_{1}=\mathrm{a}_{1} \cdots \mathrm{a}_{i}$ and $\beta_{2}=\mathrm{a}_{i+1} \cdots \mathrm{a}_{n}$ are both palindromes. However, flipping $\mathrm{a}_{j}$ to 0 to obtain $\alpha$ implies that $\alpha$ is greater than or equal to the necklace in $\left[\alpha^{R}\right]$, contradicting the assumption that $\alpha$ is an apalindromic bracelet. Thus, last $0(\alpha)$ is an apalindromic bracelet.

Figure 2 The cycle-joining tree $\mathbb{T}_{9}$. The black edges indicate that $\operatorname{par}(\alpha)=$ first1 $(\alpha)$; the blue edges indicate that $\operatorname{par}(\alpha)=$ $\operatorname{last} 1(\alpha)$; the red edges indicate that $\operatorname{par}(\alpha)=\operatorname{last} 0(\alpha)$.

Consider last1 $(\operatorname{last} 0(\alpha))=0^{s+1} 1 \beta 1^{v}$. Let $\beta=\mathrm{b}_{1} \mathrm{~b}_{2} \cdots \mathrm{~b}_{m}$. Suppose that $m=0$. Then last1(last0 $\left.(\alpha)\right)=$ $0^{s+1} 1^{v+1} \Longrightarrow \operatorname{last} 0(\alpha)=0^{s} 1^{v+1}$. Since $v=1$ or $v=2$, we have that last $0(\alpha)=0^{s} 11$ or last $0(\alpha)=0^{s} 111$. Now $\alpha$ is the result of flipping one of the 1 s in $\operatorname{last} 0(\alpha)$ to a 0 and performing the appropriate rotation. But in every case, we end up with $\alpha$ being a palindromic necklace, a contradiction. Thus, assume $m \geq 1$. Suppose $\beta=1^{m}$. Then, $\alpha$ is not an apalindromic bracelet, a contradiction. Suppose $\beta=0^{m}$. If $v=1$, then $\alpha$ is palindromic, a contradiction; if $v=2$ then last $1(\operatorname{last} 0(\alpha))=0^{s+1} 10^{m} 11$ which is in $\mathbf{A}(n)$. For all other cases, $\beta$ contains at least one 1 and at least one $0 ; m \geq 2$. Since $\beta$ does not contain $0^{s+1}$ as a substring, by Lemma 2, we must show that (i) $\mathrm{b}_{1} \cdots \mathrm{~b}_{m} 1^{v-1}$ is less than its reversal $1^{v-1} \mathrm{~b}_{m} \cdots \mathrm{~b}_{1}$, recalling that (ii) $\mathrm{b}_{1} \cdots \mathrm{~b}_{m} 01^{v-1}$ is less than its reversal $1^{v-1} 0 \mathrm{~b}_{m} \cdots \mathrm{~b}_{1}$. Let $\ell$ be the largest index of $\beta$ such that $b_{\ell}=1$. Then $b_{\ell+1} \cdots b_{m}=0^{m-\ell}$; note that $b_{\ell+1} \cdots b_{m}$ is the empty string when $\ell=m$. Suppose $v=1$. From (ii), $\mathrm{b}_{1}=0$. By (ii) we have $\mathrm{b}_{2} \cdots \mathrm{~b}_{\ell-1} 10^{m-\ell}<0^{m-\ell} 1 \mathrm{~b}_{\ell-1} \cdots \mathrm{~b}_{2}$. But this implies that $b_{2} \cdots b_{m-\ell+1}=0^{m-\ell}$. Therefore, we have $b_{1} \cdots b_{m}=0^{m-\ell+1} b_{m-\ell+2} \cdots b_{m}<0^{m-\ell} 1 b_{\ell-1} \cdots b_{1}=b_{m} \cdots b_{1}$, hence (i) is satisfied. Suppose $v=2$. If $\mathrm{b}_{1}=0$, then (i) is satisfied. Otherwise $\mathrm{b}_{1}=1$ and from (ii) $\mathrm{b}_{2}=0$. From (ii), we get that $b_{3} \cdots b_{\ell-1} 10^{m-\ell}<0^{m-\ell} b_{\ell-1} \cdots b_{3}$. This inequality implies that $b_{3} \cdots b_{m-\ell+2}=0^{m-\ell}$. Therefore, we have $b_{1} \cdots b_{m} 1=10^{m-\ell+1} b_{m-\ell+3} \cdots b_{m} 1<10^{m-\ell} 1 b_{\ell-1} \cdots b_{1}=1 b_{m} \cdots b_{1}$, hence (i) is satisfied. Thus, last 1 (last $\left.0(\alpha)\right)$ is an apalindromic bracelet.

Proof of Theorem 4. Let $\alpha$ be an apalindromic bracelet in $\mathbf{A}(n) \backslash\left\{r_{n}\right\}$. We demonstrate that the parent rule par from (1) induces a path from $\alpha$ to $r_{n}$, i.e., there exists an integer $j$ such that $\operatorname{par}^{j}(\alpha)=r_{n}$. Note that $r_{n}$ is the lexicographically smallest apalindromic bracelet of order $n$. By Lemma 5, $\operatorname{par}(\alpha) \in \mathbf{A}(n)$. In the first two cases of the parent rule, $\operatorname{par}(\alpha)$ is lexicographically smaller than $\alpha$. If the third case applies, let $\alpha=0^{s} 1 \beta$. From Lemma 5, last1 (last0 $\left.(\alpha)\right)$ is an apalindromic bracelet. Thus, $\operatorname{par}(\operatorname{par}(\alpha))$ is either first1 $(\operatorname{last} 0(\alpha))$ or last1 $(\operatorname{last} 0(\alpha))$; in each case the resulting apalindromic bracelet has $0^{s+1}$ as a prefix and is therefore lexicographically smaller than $\alpha$. Therefore, the parent rule induces a path from $\alpha$ to $r_{n}$.

### 3.1 A successor rule

Each application of the parent rule $\operatorname{par}(\alpha)$ in (1) corresponds to a conjugate pair. For instance, consider the apalindromic bracelet $\alpha=000101111$. The parent of $\alpha$ is obtained by flipping the last 1 to obtain 000101110 (see Figure 2). The corresponding conjugate pair is $(\mathbf{1 0 0 0 1 0 1 1 1}, \mathbf{0} 00010111)$. Let $\mathbf{C}(n)$ denote the set of all strings belonging to a conjugate
pair in the cycle-joining tree $\mathbb{T}_{n}$. Then the following is a UC-successor for an $\mathcal{O} \mathcal{S}(n)$ :

$$
f(\alpha)= \begin{cases}\overline{\mathrm{a}}_{1} & \text { if } \alpha \in \mathbf{C}(n) \\ \mathrm{a}_{1} & \text { otherwise }\end{cases}
$$

For example, if $\mathbf{C}(9)$ corresponds to the conjugate pairs to create the cycle-joining tree $\mathbb{T}_{9}$ shown in Figure 2, then the corresponding universal cycle is:

$$
\begin{aligned}
& 0000010111110010110110010111100110111 \underline{10001011100101011100011011} \\
& 101011011100001001110001001010001001100001011001001011000101011
\end{aligned}
$$

where the two underlined strings belong to the conjugate pair $(\mathbf{1 0 0 0 1 0 1 1 1 , 0 0 0 0 1 0 1 1 1 )}$. In general, this rule requires exponential space to store the set $\mathbf{C}(n)$. However, in some cases, it is possible to test whether a string is in $\mathbf{C}(n)$ without pre-computing and storing $\mathbf{C}(n)$. In our UC-successor for an $\mathcal{O} \mathcal{S}(n)$, we use Theorem 1 to avoid pre-computing and storing $\mathbf{C}(n)$, thereby reducing the space requirement from exponential in $n$ to linear in $n$.

## Successor-rule $g$ to construct an $\mathcal{O S}(n)$ of length $L_{n}$

Let $\alpha=\mathrm{a}_{1} \mathrm{a}_{2} \cdots \mathrm{a}_{n} \in \mathbf{S}(n)$ and let

- $\beta_{1}=0^{n-i} 1 \mathbf{a}_{2} \cdots \mathrm{a}_{i}$ where $i$ is the largest index of $\alpha$ such that $\mathrm{a}_{i}=1$ (first 1 );
- $\beta_{2}=\mathrm{a}_{2} \mathrm{a}_{3} \cdots \mathrm{a}_{n} \mathbf{1}$ (last 1 );
- $\beta_{3}=\mathrm{a}_{j} \mathrm{a}_{j+1} \cdots \mathrm{a}_{n} 01^{j-2}$ where $j$ is the smallest index of $\alpha$ such that $\mathrm{a}_{j}=0$ and $j>1$ (last 0 ).

Let

$$
g(\alpha)= \begin{cases}\overline{\mathrm{a}}_{1} & \text { if } \beta_{1} \text { and first1 }\left(\beta_{1}\right) \text { are in } \mathbf{A}(n) \\ \overline{\mathrm{a}}_{1} & \text { if } \beta_{2} \text { and last1 }\left(\beta_{2}\right) \text { are in } \mathbf{A}(n), \text { and first1 }\left(\beta_{2}\right) \text { is not in } \mathbf{A}(n) \\ \overline{\mathrm{a}}_{1} & \text { if } \beta_{3} \text { and last0 }\left(\beta_{3}\right) \text { are in } \mathbf{A}(n), \text { and neither first1 }\left(\beta_{3}\right) \text { nor last1 }\left(\beta_{3}\right) \text { are in } \mathbf{A}(n) \\ \mathrm{a}_{1} & \text { otherwise. }\end{cases}
$$

Starting with any string in $\alpha \in \mathbf{S}(n)$, we can repeatedly apply $g(\alpha)$ to obtain the next bit in a universal cycle for $\mathbf{S}(n)$.

- Theorem 6. The function $g$ is a UC-successor for $\mathbf{S}(n)$ and generates an $\mathcal{O S}(n)$ with length $L_{n}$ in $O(n)$-time per bit using $O(n)$ space.

Proof. Consider $\alpha=\mathrm{a}_{1} \mathrm{a}_{2} \cdots \mathrm{a}_{n} \in \mathbf{S}(n)$. If $\alpha$ belongs to some conjugate pair in $\mathbb{T}_{n}$, then it must satisfy one of three possibilities stepping through the parent rule in 1 :

- Both $\beta_{1}$ and first1 $\left(\beta_{1}\right)$ must be in $\mathbf{A}(n)$. Note, $\beta_{1}$ is a rotation of $\alpha$ when $\mathrm{a}_{1}=1$, where $\mathrm{a}_{1}$ corresponds to the first one in $\beta_{1}$.
- Both $\beta_{2}$ and last1 $\left(\beta_{2}\right)$ must both be in $\mathbf{A}(n)$, but additionally, first1 $\left(\beta_{2}\right)$ can not be in $\mathbf{A}(n)$. Note, $\beta_{2}$ is a rotation of $\alpha$ when $\mathrm{a}_{1}=1$, where $\mathrm{a}_{1}$ corresponds to the last one in $\beta_{2}$.
- Both $\beta_{3}$ and last0 $\left(\beta_{3}\right)$ must both be in $\mathbf{A}(n)$, but additionally, both first1 $\left(\beta_{3}\right)$ and last1 $\left(\beta_{3}\right)$ can not be in $\mathbf{A}(n)$. Note, $\beta_{3}$ is a rotation of $\alpha$ when $\mathrm{a}_{1}=0$, where $\mathrm{a}_{1}$ corresponds to the last zero in $\beta_{3}$.

Thus, $g$ is a UC-successor for $\mathbf{S}(n)$ and generates a cycle of length $|\mathbf{S}(n)|=L_{n}$. By Theorem 1 , one can determine whether a string is in $\mathbf{A}(n)$ in $O(n)$ time using $O(n)$ space. Since there are a constant number of tests required by each case of the UC-successor $g$, the corresponding $\mathcal{O S}(n)$ can be computed in $O(n)$-time per bit using $O(n)$ space.

## 4 Extending orientable sequences

The values from the column labeled $L_{n}^{*}$ in Table 1 were found by extending an $\mathcal{O S}(n)$ of length $L_{n}$ constructed in the previous section. Given an $\mathcal{O S}(n), \circ_{1} \cdots o_{m}$, the following approaches were applied to find longer $\mathcal{O S}(n)$ s for $n \leq 20$ :

1. For each index $i$, apply a standard backtracking search to see whether $o_{i} \cdots o_{m} o_{1} \cdots o_{i-1}$ can be extended to a longer $\mathcal{O S}(n)$. We followed several heuristics: (a) find a maximal length extension for a given $i$, and then attempt to extend starting from index $i+1$; (b) find a maximal length extension over all $i$, then repeat; (c) find the "first" possible extension for a given $i$, and then repeat for the next index $i+1$. In each case, we repeat until no extension can be found for any starting index. This approach was fairly successful for even $n$, but found shorter extensions for $n$ odd. Steps (a) and (b) were only applied to $n$ up to 14 before the depth of search became infeasible.
2. Refine the search in the previous step so the resulting $\mathcal{O S}(n)$ of length $m^{\prime}$ has an odd number of 1 s and at most one substring $0^{n-4}$. Then we can apply the recursive construction by Mitchell and Wild [25] to generate an $\mathcal{O} \mathcal{S}(n+1)$ with length $2 m^{\prime}$ or $2 m^{\prime}+1$. Then, starting from the sequences generated by recursion, we again apply the exhaustive search to find minor extensions (the depth of recursion is significantly reduced). This approach found significantly longer extensions to obtain $\mathcal{O S}(n+1)$ s when $n+1$ is odd.

## 5 Future research directions

We present the first polynomial time and space algorithm to construct orientable sequences with asymptotically optimal length; it is a successor-rule-based approach that requires $O(n)$ time per bit and uses $O(n)$ space. This answers a longstanding open question by Dai, Martin, Robshaw, and Wild [6]. The following questions are currently being addressed. (1) How can our parent rule be generalized to an arbitrary alphabet like $\{C, G, A, T\}$. The notion of orientation is especially applicable in areas of computational biology [7, 18]. (2) Can the recent concatenation tree framework [27] be applied to construct our $\mathcal{O S}(n)$ s in $O(1)$-amortized time per symbol? Additional interesting questions and problems include:

1. Can the lower bound of $L_{n}$ for orientable sequences be improved?
2. Can small strings be inserted systematically into our constructed $\mathcal{O S}(n)$ s to obtain longer orientable sequences?
3. Can our $\mathcal{O S}(n)$ s be used to find longer aperiodic orientable sequences than reported in [4]?
4. A problem closely related to efficiently generating long $\mathcal{O S}(n)$ s is the problem of decoding or unranking orientable sequences. That is, given an arbitrary length- $n$ substring of an $\mathcal{O S}(n)$, efficiently determine where in the sequence this substring is located. There has been little to no progress in this area. Even in the well-studied area of de Bruijn sequences, only a few efficient decoding algorithms have been discovered. Most decoding algorithms are for specially constructed de Bruijn sequences; for example, see [24, 32]. It seems hard to decode an arbitrary de Bruijn sequence. The only de Bruijn sequence whose explicit construction was discovered before its decoding algorithm is the lexicographically least de Bruijn sequence, sometimes called the Ford sequence in the binary case, or the Granddaddy sequence (see Knuth [19]). Algorithms to efficiently decode this sequence were independently discovered by Kopparty et al. [21] and Kociumaka et al. [20]. Later, Sawada and Williams [28] provided a practical implementation.
